The Department of Bioengineering at the University of Pittsburgh Swanson School of Engineering invites applications from accomplished individuals with a PhD or equivalent degree in bioengineering, biomedical engineering, or closely related disciplines for an open-rank, tenured/tenure-stream faculty position. We wish to recruit an individual with strong research accomplishments in Translational Bioengineering (i.e., leveraging basic science and engineering knowledge to develop innovative, translatable solutions impacting clinical practice and healthcare), with preference given to research focus on neuro-technologies, imaging, cardiovascular devices, and biomimetic and biorobotic design. It is expected that this individual will complement our current strengths in biomechanics, bioimaging, molecular, cellular, and systems engineering, medical product engineering, neural engineering, and tissue engineering and regenerative medicine. In addition, candidates must be committed to contributing to high quality education of a diverse student body at both the undergraduate and graduate levels.

[CLICK HERE FOR FURTHER DETAILS](#)

**To ensure full consideration, applications must be received by June 30, 2019. However, applications will be reviewed as they are received. Early submission is highly encouraged.**

## Abstract

This study presents a new automatic spike sorting method based on feature extraction by Laplacian eigenmaps combined with  $k$ -means clustering. The performance of the proposed method was compared against previously reported algorithms such as principal component analysis (PCA) and amplitude-based feature extraction. Two types of classifier (namely  $k$ -means and classification expectation-maximization) were incorporated within the spike sorting algorithms, in order to find a suitable classifier for the feature sets. Simulated data sets and *in-vivo* tetrode multichannel recordings were employed to assess the performance of the spike sorting algorithms. The results show that the proposed algorithm yields significantly improved performance with mean sorting accuracy of 73% and sorting error of 10% compared to PCA which combined with  $k$ -means had a sorting accuracy of 58% and sorting error of 10%.

## 1. Introduction

Neurons are the principal cellular elements that underlie the function of the nervous system, which includes the brain, spinal cord, and peripheral ganglia. These electrically excitable cells process and transmit information mainly by electrical signalling through the generation of action potentials [1]. These action potentials can be recorded *in vivo* by placing electrodes in the vicinity of the neuron's membrane within the extracellular space. The design of the electrodes used in extracellular recordings may vary from single wire, tetrode (four wires twisted together) to microelectrode array configurations.

Although the electrodes' configuration can differ from one experiment to another, the basic principle behind action potential sampling remains the same. Electrodes measure electric potential fluctuations in the extracellular space. These fluctuations generally contain two types of activity, low

frequency content, also known as local field potentials (LFPs), and extracellular action potentials (spikes) which contribute to the higher frequency content [2]. The spikes recorded by the electrodes represent spike events generated by an unknown number of neurons. The role of spike sorting is therefore to assign each spike to the neuron that produced it [3]. As the technology progresses multi-electrode arrays are increasingly being employed [4, 5]. Increasing the number of recording electrodes raises the need for automatic sorting, as manual sorting or human supervised sorting becomes a time-consuming and tedious task.

The complexity of spike sorting can be attributed to several factors. It has been reported that spike waveforms for a given neuron can vary [6]; for example, during a complex spike burst, the amplitude of the spike can decrease by up to 80% [7]. Overlapping spikes create another complication when it comes to spike sorting; this phenomenon occurs when two or more closely spaced neurons fire action potentials simultaneously.

**Figure 1.** Illustration of the steps involved in spike sorting.

Moreover, in the course of the recording session, the electrode may move slightly within the brain tissue due to external physical constraints, causing the spike waveform to vary in time [8].

Spike sorting algorithms are typically composed of four steps in total (figure 1). The first step involves detecting spike segments. The second step consists of extracting features that best discriminate the spikes produced by the different neurons. In the third step the number of neurons is estimated and often this step is carried in conjunction with the final step. In the final step each spike is assigned to the neuron that generated it.

Spike detection methods reported in the literature include amplitude thresholding [9–11] and a nonlinear energy operator [12, 13]. In the feature extraction step, parameters are computed from the spike that yields the best discrimination. The clustering step then groups the spikes with similar features together. In the literature, feature extraction methods range from simple approaches, such as extracting peak-to-peak amplitude and width of the spike, to more advanced methods such as principal component analysis (PCA) [8] which is widely used [14–17]. Harris *et al* [14] employed PCA features in conjunction with Bayesian classification (AutoClass) [18]. In [15] template matching was employed to achieve spike labelling. A combination of wavelet transform and *k*-means clustering was employed in [19]. Wavelet transform combined with superparamagnetic clustering was reported in [9]. In [20] independent component analysis (ICA) and *k*-means clustering were employed. Waveform derivatives with the evolving mean shift clustering algorithm were proposed in [13]. In the literature a variety of methods are proposed to improve spike sorting algorithms. Improvement in spike sorting algorithms allows the isolation of a larger number of spike clusters; hence maximizing the information extracted from *in-vivo* spike recordings.

In this study a robust method of automatic spike sorting is proposed based on the combination of Laplacian eigenmaps (LE) feature extraction and the *k*-means clustering algorithm. The performance of the proposed method is compared with systems based on simple amplitude features and on PCA-derived features. Two types of classification algorithms were employed in this study, namely *k*-means and classification expectation-maximization algorithms (CEM, as implemented in KlustaKwik [21]).

## 2. Data set

Simulated data used in this study were obtained from the publicly available data set Wave\_clus [9]. Eight simulated recordings (named A–H in table 1) were employed in this study, including simulations of complex spike cells (data set B) and electrode drift (data set D). All simulated data sets in our study included overlapping spikes. On average, the percentage of overlapping spikes accounts for 20% of the overall spike population. Each file contains spikes from three neurons. The average number of neural spikes in the files was  $\sim 3450$ . Standard deviation of noise in the data set varied between 5% and 20% of the spike peak amplitude. The noise was constructed to simulate background neural activity. This was achieved by adding average spike waveforms at random times and with random amplitudes to form the noise signal. The simulated data spike clusters had a mean firing rate of 20 Hz and a 2 ms refractory period.

Simulated data have the advantage of being objective and it provides an error-free benchmark. However, it has several shortcomings. For example, the simulated data represent a single channel recording. However it has been established that multichannel recording such as tetrodes markedly improves spike sorting [22]. Hence, it is vital to consider multichannel recording when assessing the performance of spike sorting algorithms.

The simulated data sets in this study contained spikes from three neurons in each recording; however when it comes to *in-vivo* studies, more neurons may be recorded by each channel. Theoretical estimations suggest that a tetrode can sense spikes from  $\sim 140$  neurons with sufficient spike amplitude for spike sorting [23]. In practice, however, the number of neurons sensed will be fewer  $\sim 20$  [23]. A higher number of clusters

**Table 1.** Simulated data set results.

Data set	<i>k</i> -means classifier						CEM classifier					
	LE features		PCA features		Amplitude-only features		LE features		PCA features		Amplitude-only features	
	SA (%)	SE (%)	SA (%)	SE (%)	SA (%)	SE (%)	SA (%)	SE (%)	SA (%)	SE (%)	SA (%)	SE (%)

mean	73	10	58	19	57	37	72	14	52	47	62	37

can lead to lower classification accuracy. For example, if there are two clusters, the probability of classifying an object correctly by chance is 50%, while if the number of clusters increases to 10, then the probability is reduced to 10%.

To address the shortcomings of the simulated data set, we have also evaluated the performance of spike sorting algorithms on *in-vivo* recording from the hippocampus of a freely moving rodent. A surgical procedure was followed for the implantation of electrodes; the animal was anaesthetized with isoflurane and mounted on a stereotaxic frame for precise positioning of the electrodes (see [24] for further details). The animal was allowed to freely explore an enclosure for 20 min during the recording. Experiments were conducted in accordance with European Community directive, 86/609/EC, and the Cruelty to Animals Act, 1876, and followed Bioresources Ethics Committee, Trinity College, Dublin, Ireland, and international guidelines of good practice.

The *in-vivo* data were collected using a commercial spike recording system (Axona, Ltd). The recording was obtained using a tetrode configuration with one channel set as a reference. In this case, the results of automatic sorting were compared against expert manual sorting. The expert was able to sort and reliably isolate spikes of two neurons (~3890 spikes). The remaining detected segments were considered as noise events. The total number segments detected (noise and spikes) was ~10400. Manual spike sorting was carried out offline using graphical cluster-cutting software (Axona, Ltd). The spike sorting performance using *in-vivo* data provides an insight into the performance of the spike sorting algorithms for practical spike sorting by the scientific community.

### 3. Methods

Spike sorting involves four steps (see figure 1) as follows.

#### 3.1. Spike detection

The spike detection employed in this study was based on the method reported in [9]. The recordings were high-pass filtered (300 Hz). The background noise standard deviation was estimated using the formula below:

$$\sigma_{\text{noise}} = \frac{\text{median}(|x_f|)}{0.6745} \quad (1)$$

where  $x_f$  refers to the sampled filtered signal. The threshold was chosen as in [9] to be  $4 * \sigma_{\text{noise}}$ . Spikes are detected when this threshold is exceeded. Each detected spike is represented by 64 samples when the threshold was exceeded. This corresponds to ~2.7 ms.

#### 3.2. Feature extraction

Feature sets were divided into three categories.

**3.2.1. Laplacian eigenmaps.** LE is a dimension reduction method [25]. As with any data reduction method, the problem is that given a set of  $\mathbf{x}_1, \dots, \mathbf{x}_M$  of  $M$  points in  $R^l$ , find a set of point  $\mathbf{y}_1, \dots, \mathbf{y}_M$  in  $R^n$  ( $n \ll l$ ) such that  $\mathbf{y}_i$  represents  $\mathbf{x}_i$ . The objective of LE is to map points which are found to

be similar under a specific definition, to points close together [25, 26]. Let  $\mathbf{y} = (\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3, \dots, \mathbf{y}_m)^T$  be such a map, this objective is achieved by minimizing the following function:

$$\sum_{ij} W_{ij} (\mathbf{y}_i - \mathbf{y}_j)^2 \quad (2)$$

where  $W_{ij}$  is defined in equation (3). This weight function ( $W_{ij}$ ) ensures that points close to each other assigned a large weight, while points further apart assigned a smaller weight. Since this function decreases exponentially, points mapped further apart incur a heavier penalty [25]. These mappings demonstrate the potential suitability of LE in spike sorting algorithms. For a detected spike segment  $\mathbf{x}$  of a length  $M$  the LE algorithm has the following steps.

- *First step.* The Euclidean distance matrix is computed  $\|\mathbf{x}_i - \mathbf{x}_j\|^2$ . Then  $n$  nearest neighbours are connected, i.e. if node  $j$  is among the  $n$  nearest neighbours of  $i$  then nodes  $i$  and  $j$  are connected.
- *Second step.* The weight matrix is computed according to equation (3):

$$W_{ij} = \begin{cases} e^{-\frac{\|\mathbf{x}_i - \mathbf{x}_j\|^2}{2\sigma}} & \text{if } i \text{ and } j \text{ are connected} \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

- *Third step.* For the connected component the generalized eigenvalues and eigenvectors are computed:

$$L\mathbf{f} = \lambda D\mathbf{f} \quad (4)$$

where  $\lambda$  is the eigenvalue and  $\mathbf{f}$  is the corresponding eigenvector

$$\text{with } D_{ii} = \sum_j W_{ij} \quad (5)$$

$$\text{Laplacian matrix } L = D - W. \quad (6)$$

- *Fourth step.* The eigenvectors are sorted according to their eigenvalues:

$$0 = \lambda_0 \leq \lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_m. \quad (7)$$

- *Final step.* The mapping of  $\mathbf{x}_i$  into the lower  $m$  dimension space is then given by  $(\mathbf{f}_1(i), \dots, \mathbf{f}_m(i))$ , ignoring the first eigenvector  $\mathbf{f}_0$  which corresponds to the eigenvalue 0.

There are two parameters to be determined in the LE dimension reduction algorithm, namely  $n$  and  $\sigma$ . It is reported in [27, 28] that choosing  $n$  values between 5 and 21 is sufficient for spike cluster separation. In this study  $n = 12$  was chosen which is in the range reported in the literature.  $\sigma$  was determined empirically; higher values than 0.6 were shown to have no effect in improving the cluster separation. In this study  $\sigma$  was set to a simple value of 1. The dimension of the features extracted from the spikes using LE dimension reduction was limited to three dimensions, in line with the other feature extraction methods compared in this study.

**3.2.2. PCA features.** PCA finds a set of orthogonal basis vectors that represent the largest variation of the data. It has been reported for spike sorting that choosing the first three principal components provides good separation [29]. Choosing a higher number of components would account for higher variation; however, higher components were found to be dominated by background noise [8]. In this study the PCA features consisted of the first three PCA components.

**3.2.3. Amplitude-only features.** Amplitude-only features were based on the temporal characteristic of the spike waveform. The distance between the neuron and the electrode is an important factor in determining the amplitude sensed by the electrode [23, 30]. In an environment where neurons are not equidistant with respect to the electrode, the amplitude of the spikes can be used to discriminate spikes from different neurons.

The temporal characteristics extracted included

- the positive peak amplitude of the spike,
- the amplitude of the local minimum before the peak and
- the amplitude of the local minimum after the peak.

### 3.3. Clustering

Two types of clustering algorithms were used in this study.

**3.3.1. *k*-means clustering.** *k*-means clustering [31] is a simple clustering algorithm involving few steps, although the number of clusters *k* must be predetermined. In spike sorting methods, the number of neurons contributing to the spikes sensed by the electrode is not known, and therefore, it is not possible to preset *k*. To overcome this *k*-means limitation, the PBM index [32] was employed to determine *k*. The PBM index is a cluster validity index; it measures the ‘goodness’ of clustering using a range of clusters (*k*).

Below is a short description of the steps in *k*-means combined with PBM index algorithms.

- *Step 1.* Number of clusters is initially set to *k*.
- *Step 2.* *k* points are chosen randomly in the feature space as the initial cluster centres  $CC_j$  where  $j = 1, \dots, k$ .
- *Step 3.* For a feature vector  $A$  of length *N*, find the Euclidean distance between each  $A_i$  and  $CC_j$ ,  $j = 1, \dots, k$ , where  $i = 1, \dots, N$ .
- *Step 4.* Assign  $A_i$  to the cluster  $CC_j$  which gives the minimum Euclidean distance.
- *Step 5.* Recalculate cluster centres  $CC_j$  using the points in each cluster.
- The steps 2–5 are repeated until no change is obtained, below a certain threshold, in cluster centres  $CC_j$ . In practice clustering is repeated a number times with different initial random cluster centres so that a local minimum is not interpreted as the optimum classification result.
- *Step 6.* Calculate the PBM index for each *k*:

$$PBM(k) = \left( \frac{1}{k} \times \frac{E_1}{E_k} \times S_k \right)^2 \quad (8)$$

where *k* is the number of clusters,  $S_k$  is the maximum separation between cluster centres;  $E_1$  is the sum of separation between the points and the cluster centres when number clusters  $k = 1$ .  $E_k$  is the sum of separations between the feature points and the *k* cluster centres.

- *Step 7.* Choose *k* that yields the highest PBM index.

**3.3.2. Classification expectation-maximization.** We used the software KlustaKwik which is based on the CEM algorithm [33].

## 4. Performance measure metrics

Two metrics were used to evaluate the performance of the spike sorting system. Similar to [13] a classification matrix (CM) was computed. However, a modified matrix was developed to include the ‘noise events’ or non-spike events:

$$CM = \begin{matrix} & \begin{matrix} N_0 & N_1 & N_2 & N_3 & \dots & N_K \end{matrix} \\ \begin{matrix} C_1 \\ C_2 \\ C_3 \\ \vdots \\ C_k \end{matrix} & \begin{bmatrix} FP_{10} & TP_1 & FP_{12} & FP_{13} & \dots & FP_{1K} \\ FP_{20} & FP_{21} & TP_2 & FP_{23} & \dots & FP_{2K} \\ FP_{30} & FP_{31} & FP_{32} & TP_3 & \dots & FP_{3K} \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ FP_{k0} & FP_{k1} & FP_{k2} & FP_{k3} & \dots & FP_{kK} \end{bmatrix} \end{matrix} \quad (9)$$

where  $N_0$  refers to noise events, and  $N_1 N_2 N_3 \dots N_K$  reflect the spikes produced by each neuron respectively, and  $C_1, C_2$  and  $C_3 \dots C_k$  refer to the clusters identified by the spike sorting method. *K* refers to the actual number of neurons in the recording, and *k* refers to the number of clusters identified.  $TP_i$  is the number of spikes from neuron *i* in the cluster *i* (true positives).  $FP_{ij}$  is the number of spikes from neuron *j* in the cluster *i* (False positives), note that  $j = 0$  corresponds to noise events.

The first measure of performance is the sorting accuracy (SA) which is the percentage of the detected spikes labelled correctly:

$$SA(\%) = 100 * \frac{\sum_{i=1}^K TP_i}{\sum_{i=1}^K TP_i + \sum_{i,j=1,i \neq j}^K FP_{ij}}. \quad (10)$$

Sorting error (SE) is the ratio of the false positives to the total number of segments (spikes and noise) in identified clusters:

$$SE(\%) = 100 * \frac{\sum_{i=1,j=0,i \neq j}^K FP_{ij}}{\sum_{i=1}^K TP_i + \sum_{i=1,j=0,i \neq j}^K FP_{ij}}. \quad (11)$$

A perfect spike sorting algorithm will yield a SA of 100% and SE of 0% which corresponds to  $\sum_{i=0,j=1,i \neq j}^k FP_{ij} = 0$ .

## 5. Results

### 5.1. Spike detection

The performance of the spike detection method was assessed based on the percentage of neural spikes detected correctly. In this study the mean percentage of neural spikes detected was 92% with a standard deviation of 10%. The percentage noise events is defined as the ratio of the noise events to the total number of segments detected (noise and neural spikes). The mean noise percentage was 2% and the standard deviation was 4%.

### 5.2. Spike sorting using the simulated data set

The three feature extraction processes mentioned in the previous section were applied to the simulated data set and both types of classifiers were used to cluster the feature data. The results are shown in table 1.

When comparing the mean performance metrics in the last row of table 1, it is evident that LE combined with *k*-means

**Figure 2.** Dot plot of the sorting accuracy result obtained using the spike sorting methods. Each dot represents the sorting accuracy of a single simulated data set using the corresponding spike sorting method on the  $x$ -axis. Horizontal lines represent the mean sorting accuracy of the spike sorting method.

**Figure 3.** Dot plot of the sorting error results obtained using the spike sorting methods. Each dot represents the sorting error of a single simulated data set using the corresponding spike sorting method on the  $x$ -axis. Horizontal lines represent the mean sorting error of the spike sorting method.

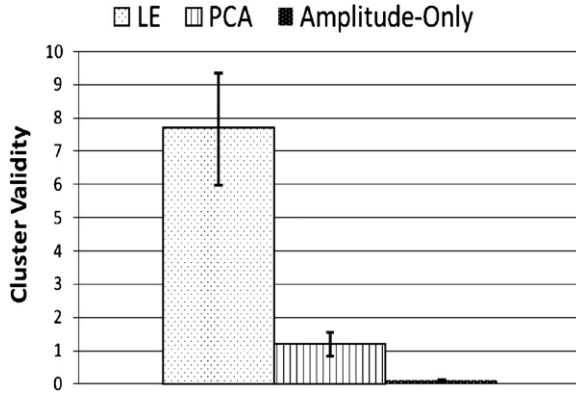

classification yields higher SA and lower SE percentages than other methods. By examining the mean performances, it can be concluded that amplitude-only features perform poorly when compared to other methods. The mean performance in table 1 also illustrates that the  $k$ -means classification is more suitable to PCA feature extraction than the CEM algorithm.

The Friedman test [34] was employed to assess if the methods produced significant improvement. This test can be used to determine if there is a significant difference between several methods when the different methods were tested on the same data [35].

The Friedman test revealed that the sorting accuracies percentages were significantly different with ( $p < 0.0427$ ). *Post hoc* analysis showed that LE combined with  $k$ -means or CEM yields significant different performance than amplitude-only features when used with both clustering methods and PCA combined with CEM. Applying the Friedman test

to SE percentages showed that the sorting algorithms are significantly different ( $p < 0.0005$ ). *Post hoc* analysis reveals that LE methods yield significantly lower SE than the other methods compared in this study. However no significant differences were found between the two classifiers when LE features were extracted. The test also confirms that PCA combined with  $k$ -means provides less SE than the combination of PCA, CEM clustering, and algorithms based on amplitude-only features. Figure 2 presents a graphical representation of the SA of the spike sorting algorithms employed in this study. Figure 3 on the other hand shows the comparison of the SE percentages of the algorithms.

To further test the effectiveness of LE feature extraction. The ratio of the between-cluster to the within-cluster distance (cluster validity) was compared to other features extraction methods employed in this study (figure 4). Similarly Ganbari *et al* [27] have tested this ratio and their results showed that

**Figure 4.** Comparison of mean cluster validity index for the feature extraction methods, vertical lines indicate standard error.

LE clusters were better separated than PCA clusters:

$$\text{Cluster Validity} = \frac{\min_{i=1,2,\dots,K, j=i+1,\dots,K} (\|CC_i - CC_j\|^2)}{\frac{1}{N_i} \sum_{i=1}^K \sum_{A \in N_i} \|A - CC_i\|^2} \quad (12)$$

where  $CC_i$  is the centre of cluster of spikes produced by neuron  $N_i$ ,  $N_i$  is the total number of spikes,  $K$  is the number of neurons simulated in the recording, and  $A$  is the feature vector. This cluster validity represents the ratio of the between-cluster to the within-cluster distance. Higher cluster validity indicates better separation. As shown in figure 4 the mean cluster validity is higher for LE features compared to the other features employed in the study. The differences in cluster validity between all methods are statistically significant ( $p < 0.0001$ ) as indicated by the Friedman test.

Figures 5 and 6 show the two-dimensional feature space for the simulated data set C. Figures 5(a) and 6(a) show the feature space of the simulated data with three clusters ( $\circ$ ,  $+$ ,  $\diamond$ ),

each point represents the spike produced by the neuron. The markers and colours are used to identify the neuron to which the spike belongs. Figure 5(a) shows the PCA feature space and figure 6(a) shows the feature space using LE. The separation of the spike clusters is evident in LE feature space while on the other hand clusters overlapped in PCA feature space. In some cases, (as shown in figure 6(b)), over-clustering occurs. The blue cluster ( $\circ$ ) in figure 6(a) is divided into two clusters ( $\circ$  and  $\Delta$ ). The performance of the spike sorting algorithms can be improved by additional step that assesses the similarity of the spikes in each cluster and merges the cluster of spikes that belong to a single neuron. Over-clustering is also illustrated in figure 5(b).

### 5.3. Spike sorting results using in-vivo recordings

Table 2 shows the results obtained from the *in-vivo* recordings. The spike sorting algorithms were initially used to sort data of individual tetrode channels. The last row of the table (multichannel) shows the results obtained when the information is extracted from all three available channels of the tetrode and employed in the sorting algorithms. Features were extracted from each available channel and input to the classifiers. For example, in the PCA feature set the first three components from each channel were computed. Recordings from three channels were available hence the feature space included ( $3 \times 3 = 9$ ) dimensions.

SA' and SE' refer to the SA and SE when the spike sorting algorithm was compared to the expert's sorting. The results in table 2 illustrate that the combination of LE features and  $k$ -means clustering yields best sorting performance. In the combination case most of the methods yield improved performance; this illustrates the advantages of tetrode recording. All the spike sorting algorithms performed relatively poorly while sorting the spikes in the first channel; this is attributed to the low amplitude of the spikes in this channel.

**Figure 5.** PCA feature space plots for data set C, where PCA1 and PCA 2 refers to the first and second principal component, respectively. (a) PCA feature space of the spikes. (b) PCA feature extraction combined with the  $k$ -means clustering algorithm output where the PBM index has detected five clusters.

**Figure 6.** Laplacian eigenmaps feature space plots for data set C, where LE1 and LE2 refer to the first and second eigenvectors ( $f_1$  and  $f_2$ ), respectively. (a) LE feature space of the spikes. (b) LE feature extraction combined with the  $k$ -means clustering algorithm output where the PBM index has detected four clusters.

**Table 2.** *In-vivo* data set results.

## 6. Discussion

Recently it was reported that LE could aid graphical manual spike sorting [27, 28]. In this paper we extended these findings and propose a fully automated spike sorting algorithm based on LE feature extraction. The results in table 1 illustrate that there is significant improvement between LE sorting algorithms and other automatic sorting algorithms compared in this study.

It can be concluded from the results in table 1 that LE provides the best performance in spike sorting when used in combination with  $k$ -means clustering. LE combined with CEM also yields good results in spike sorting. Table 2 shows the results obtained using *in-vivo* recordings confirming the robustness of LE algorithms. However, the performance difference between CEM and  $k$ -means algorithms is profoundly more evident when used with LE features. This is primarily due to over-clustering caused by CEM. The CEM algorithms implemented in KlustaKwik assume a Gaussian distribution for the features; however the LE features do not follow the Gaussian distribution. This could explain the ineffectiveness of the LE/CEM combination.

The amplitude-only feature set yielded the poorest performance with large SE percentages as demonstrated in table 1. This may be due to electrode drift or complex-spike cells, whilst in other cases the spikes of two neurons

may have similar spike amplitude but different widths. The variation in a single neuron amplitude can cause low spike sorting performance. In the case of *in-vivo* recording results (table 2), individual channels yield high SE percentages or low SA. However, when the information from multichannel recording is extracted, the performance of spike sorting using the simple amplitude features increases, thus illustrating the importance of multichannel recording in spike sorting.

The PCA feature set yields an improved performance when combined with the  $k$ -means algorithm. However when PCA provides large cluster separation for example in simulated data sets (A, F), the SA of CEM and PCA is greater than 90% with a low percentage SE (below 4%). On the other hand, PCA feature extraction and CEM failed to cluster the other data sets properly. The results in table 2 demonstrate that PCA features when used in combination with the CEM algorithm provide better cluster separation than by PCA- $k$ -means combination. This is mainly attributed to over-clustering in the spike sorting algorithms. For example this is the main factor contributing to the low SA in the combination of channels. Using the PCA and the  $k$ -means algorithm, merging clusters can increase the SA in this case up to ~99%.

In some cases (as shown in figure 5(b)), over-clustering occurs. The performance of the spike sorting algorithms can be improved by an additional step that assess the similarity

of the spikes in each cluster and merge the cluster of spikes that belong to a single neuron. A human operated method for merging spike clusters based on autocorrelograms and cross-correlograms is proposed in [14]. Over-clustering was encountered in [13] and clusters were merged based on boundary density estimation. Over-clustering is a challenge in spike sorting that has to be addressed. A possible solution to over-clustering is to consider the eigengap heuristic [36], where the ratio of successive eigenvalues can indicate the number of clusters in a data set.

Overlapping spikes is one of the important challenges in automated spikes sorting algorithms. Several methods have been proposed in the literature addressing this problem explicitly. One approach [37] has been cited as computationally expensive, while others have proposed solutions which require less computation power [38]. However these algorithms assume Gaussian noise [39]. Recently, advancement in field has been reported [19, 39–41]. The proposed spike sorting system in this study does not explicitly deal with overlapping spikes. Algorithms that will resolve overlapping spikes in addition to the current method proposed in this study may lead to improved performance of the spike sorting system.

## 7. Conclusion

In this study, an automatic spike sorting method is proposed which is capable of spike detection, identifying the number of neurons recorded and assigning each spike to the neuron that produced it. This method yields significantly improved performance compared to previously reported methods. The method has the limitation of over-clustering in certain cases. In future studies unsupervised clustering methods will be considered to address this issue.

## Acknowledgments

This study employed a modified version of the analysis software FIND [42].
